## Abstract

In this work, the response of temperate coniferous forests to ozone air pollution ( $O_3$ ) in the mountain environment of the High Tatra Mts. (Western Carpathians) was analyzed. The modelling of stomatal  $O_3$  flux is a complex method for the estimation of phytotoxicity of  $O_3$  pollution to forest vegetation. Stomatal flux-based critical levels (*CLef*) for effects of  $O_3$  on radial growth take into account the varying influences of  $O_3$  concentration, meteorological variables, soil properties, and phenology. The application of the model  $DO_3SE$  (Deposition of Ozone for Stomatal Exchange) at five experimental plots with altitudes varying from 810 to 1,778 m a.s.l. along vertical and spatial profile in the High Tatra Mts. revealed the high phytotoxic potential of  $O_3$  on spruce forests during the growing season 2014. The accumulated stomatal  $O_3$  flux above a threshold of  $Y$  ( $1 \text{ nmol m}^{-2} \text{ s}^{-1}$ ), i.e.  $POD_1$  (Phytotoxic Ozone Dose) ranged from  $13.6 \text{ mmol m}^{-2}$  at the Kolové pleso site (1,570 m a.s.l.) to  $16.2 \text{ mmol m}^{-2}$  at Skalnaté Pleso site (1,778 m a.s.l.). *CLef* for  $POD_1$  ( $8 \text{ mmol m}^{-2}$ ) recommended for the protection of spruce forests were exceeded at all experimental plots from early July. Similarly, AOT40 index suggests vulnerability of mountain forests to  $O_3$  pollution. AOT40 values increased with altitude and reached values varying from 6.2 ppm h in Stará Lesná (810 m a.s.l.) to 10.7 ppm h at Skalnaté Pleso close to the timber line (1,778 m a.s.l.). Concentration-based critical level (*CLec*) of 5,000 ppb h was exceeded from June to August and was different for each experimental site.

**Key words:** mountain forests; Phytotoxic Ozone Dose<sub>y</sub>;  $DO_3SE$  model; stomatal conductance; stomatal ozone flux

## 1. Introduction

Ozone levels in Europe are rather high to jeopardize human health and vital growth of vegetation (WHO 2008; Paoletti 2014; Monks et al. 2015). Relevant reduction of  $O_3$ -precursors emissions in Europe (Vestreng et al. 2004) tends to decrease  $O_3$  maxima and increase annual averages at both urban and rural sites (Paoletti et al. 2014) due to less  $O_3$  titration by reduced  $NO_x$  emissions. The ozone levels are increasing in cities and decreasing at Mediterranean remote sites (Sicard et al. 2013). However, cumulative indices such as SOMO35 and AOT40, i.e. 5,000 ppb h (Directive 2008/50/EC) indicate that rural highland sites of Europe are more vulnerable to health and environmental risks associated with perpetual  $O_3$  exposure than urban lowland areas (Bičárová et al. 2013). Concentration-based critical level (*CLec*) of AOT40 for forest ecosystems is regularly exceeded in almost whole territory of Slovakia (Pavlendová 2008) as well as in the Czech Republic (Hůnová & Schreiberová 2012; Hůnová et al. 2016). At high-altitude stations, the background  $O_3$  levels (chronic exposure) are higher, and higher  $O_3$  concentrations are observed at night (Sicard et al. 2009). Acute exposures are characterized by high  $O_3$  concentrations for a relatively short time period, within hours or days that lead to visible foliar injury (Schaub et al. 2010; Sicard et al. 2011). Chronic exposures involve lower concentrations that persist or recur over a period of weeks or months (Grulke et al. 2007). Mountains can act as cold-traps for long-range transport of atmospheric pollutants. The mechanism of transport of pollutants through the atmosphere

and accumulation in the mountain environment were well described in literature (Steinbacher et al. 2004; Sicard et al. 2009, 2011; Monks et al. 2015). For example, there is evidence of accumulation of persistent organic pollutants (POPs) in the mountainous environment (Hageman et al. 2015). The highest deposition fluxes of organochlorine compounds (OCs) were found at high-altitude European sites, especially at Skalnaté Pleso in the High Tatra Mts. (Arellano et al. 2015).

Tropospheric ozone acts as a phytotoxin which produces an oxidative stress in plants. The phytotoxic nature of  $O_3$  can impair forest productivity by both favouring stomatal closure and impairing stomatal control. High  $O_3$  concentrations reduce carbon assimilation in trees while this reduction is more related to stomatal  $O_3$  deposition than to  $O_3$  concentration (Fares et al. 2013). The scientific community is moving toward an evaluation of the ozone risk based on stomatal  $O_3$  fluxes (Matyssek et al. 2007; UN-ECE 2010; Mills et al. 2011; Büker et al. 2012). Tracking of stomatal  $O_3$  uptake by vegetation required more comprehensive methods than the evaluation of  $O_3$  concentration data alone. Multiplicative models of stomatal conductance, such as the  $DO_3SE$  (Deposition of Ozone and Stomatal Exchange), have been suggested as a basis for calculating the hourly  $O_3$  flux resulted to the Phytotoxic Ozone Dose ( $POD_y$ ) (Emberston et al. 2000). For forest trees, stomatal flux-based critical levels (*CLef*) of  $POD_y$  were derived for effects on changes in annual increments in the whole tree biomass. These critical levels can be used to refer adverse health effects of  $O_3$  on

\*Corresponding author. Zuzana Sitková, e-mail: [sitkova@nlcsk.org](mailto:sitkova@nlcsk.org), phone: +421 5314 158

relevant ecosystem services provided by forest trees, e.g. production of roundwood, C sequestration, soil stability and flood prevention (Mills et al. 2011). Main problem is that present exposure-based standards for protecting vegetation from ozone ( $O_3$ ) do not reflect the actual field conditions. Recent knowledge resulting from epidemiological assessment of forest responses to  $O_3$  showed that a risk assessment based on  $POD_V$  and on real plant symptoms is more appropriate than the concentration-based method and developed the new flux-based critical levels  $CLef$  for forest protection against visible  $O_3$  injury (Sicard et al. 2016).

Previous studies concerning the problems of air quality pointed to the high level of ozone air pollution in the Western Carpathian Mts. that is comparable with the most polluted regions in Europe (Bytnerowitz et al. 2004; Bičárová et al. 2013; Hůnová et al. 2016). Formation of  $O_3$  in mountain regions of Slovakia is substantially influenced by long-range transport of  $O_3$  precursors and their interaction with local components from both antropogenic and biogenic sources (Bičárová et al. 2005). It can be expected that high chronic  $O_3$  exposure and  $O_3$  uptake by vegetation may impair the vitality of forests, especially in wet and cold climate conditions of highland areas.

The aim of this work is to quantify phytotoxic ozone dose for coniferous forest species, especially Norway spruce (*Picea abies* L. Karst) in the mountain environment of the High Tatra Mts. (Slovakia). Stomatal  $O_3$  fluxes and  $POD_1$  are calculated by  $DO_3SE$  model for five experimental sites situated along spatial and vertical profiles from 810 to 1,778 m a.s.l. during the vegetation season 2014. The results are intended to support new complex approach in research of adverse impact of  $O_3$  pollution on forest vegetation based on modelling of stomatal  $O_3$  flux. This new approach may improve still prevalently used  $O_3$  concentration based method associated with AOT40 indicator for the protection of vegetation and forests. Presented research can provide many

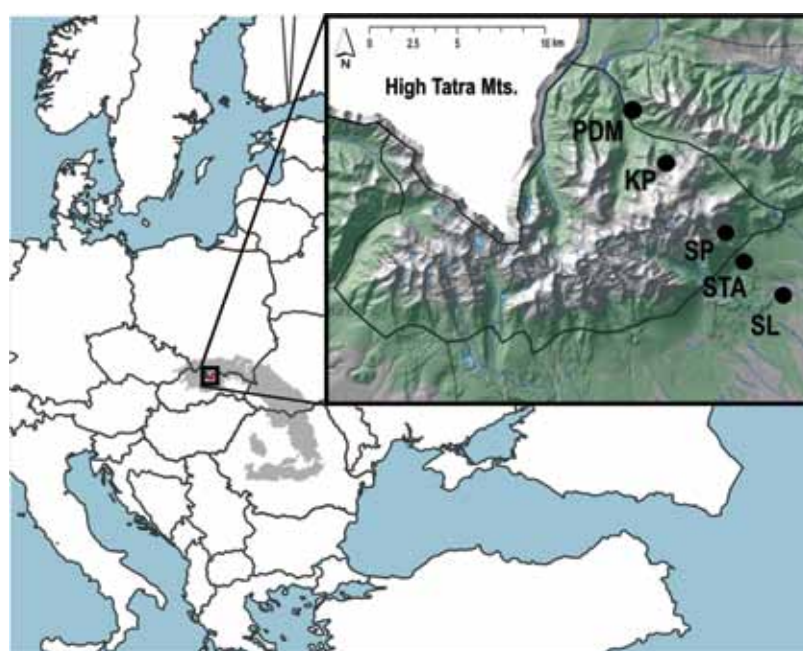

results useful for the wide scientific community (in environmental and forest science, physiological and biological research, ecological modelling etc.). Research activities and field measurements are part of the ongoing project MapPOD (Mapping of Phytotoxic Ozone Dose in the Forest Environment of the High Tatra Mts.) which focuses on assessment of potential  $O_3$  risk to mountain forests in Slovakia.

## 2. Material and methods

### 2.1. Study area

The High Tatra Mts. are located in the northern part of Slovakia on the border with Poland (Fig. 1). Region of interest represents the highest part in the whole Carpathian Mountains. The elevation of the main mountain chain of the High Tatra Mts. varies from about 2,000 m a.s.l. (saddles) to 2,654 m a.s.l. (the highest peak). Temperate coniferous forest with Norway spruce (*Picea abies* L. Karst.) is the dominant vegetation type up to 1,500 m a.s.l. From the other tree species occur European larch (*Larix decidua* Mill.), Scots pine (*Pinus sylvestris* L.) and Grey alder (*Alnus incana* L. Moench). The higher part of the valley (subalpine) is almost completely covered by Dwarf pine (*Pinus mugo* Turra).

In order to model  $O_3$  fluxes, the  $O_3$  concentrations, meteorological and environmental parameters were measured at 3 experimental sites situated in the south aspect: Stará Lesná – SL, Štart – STA, Skalnaté Pleso – SP (Table 1, Fig. 1). On the north side of the High Tatra Mts., in the vicinity of Tatranská Javorina municipality, the other 2 experimental sites (Podmuráň – PDM and Kolové pleso – KP) are located. On the south side, the massive rocky branches separate numerous glacial valleys including Skalnatá dolina area. Due to strong rain-shadow effect the climate of south-facing Skalnatá dolina area is slightly warmer and significantly drier

**Fig. 1.** The geographical position of the High Tatra Mts. in the Carpathian Montane Forests and location of the experimental sites (SL – Stará Lesná, STA – Štart, SP – Skalnaté Pleso, KP – Kolové pleso, PDM – Podmuráň).

Used data sources:

1 – forestry databases of National Forest Centre in Zvolen (soil, geological and typological maps, Forestry GIS-databases).

2 – climate data provided by Slovak Hydrometeorological Institute for the reference period 1961–1990 and Climate Atlas of Slovakia (SHMI 2015).

3 – soil units according to WRB Soil Classification System (WRB 2015, FAO).

4 – forest typology and edaphic-trophic units based on Zlatník's geobiocenological school (Zlatník 1976).

Abbreviations: AT – air temperature; P – precipitation.

compared to north part of the High Tatra Mts. (Table 1). On the contrary, the climate of the north-facing Tatranská Javorina area is cold and very wet with long-term mean annual temperatures around 3.8 °C and rainfall total of 1,250 mm at the altitude of 1,100 m a.s.l. The meteorological observation during the last two decades revealed moderate warming and increasing rainfall amounts (SHMI 2015).

In recent decades, the area of interest was affected by large-scale disturbances in connection with the adverse effects of climate change. The extreme weather conditions more frequently observed in the recent years (drought, heat waves, snow cover decline etc.) contributed to the massive bark beetle outbreaks (*Ips typographus*) in forest stands weakened by abiotic destructive factors as windstorm, fire, flooding, long-range transport of air pollutants etc. (Mezei et al. 2014; Nikolov et al. 2014).

## 2.2. Meteorological and ozone data

The basic meteorological variables (such as air temperature, relative humidity, wind speed, wind direction, solar radiation and precipitation) were continuously monitored at all experimental sites using automatic weather stations (EMS Brno CZ; Physicus, s. r. o. SK). The measuring interval of meteorological data was set on variable time step (starting from 10 seconds up to 5–10 minutes) and average data were consequently stored every 10 to 30 minutes into the central datalogger of the weather station.

Ozone concentration data were measured at five experimental sites using the ozone analyzers based on the well established technique of absorption of UV light at 254 nm. At three experimental forest sites (Stará Lesná – SL, Skalnáté Pleso – SP, Podmuráň – PDM), the analyzers manufactured by Horiba (APOA360 Ambient Ozone Monitor) and Thermo Electron Environmental (49C Ozone Analyzer) were used. The more remote experimental sites where the electricity was unavailable (Štart – STA, Kolové pleso – KP) were equipped by Ozone Analyzer Monitor M106-L (2B Technologies, Inc.) and powered by solar energy. The ozone data in default ppb units were measured in 6–10 second interval and hourly averages were stored into the datalogger. For purposes of this study, the hourly meteorological and O<sub>3</sub> concentration data from the period of April to October of the year 2014 were processed and analysed.

## 2.3. DO<sub>3</sub>SE model

The multiplicative deposition DO<sub>3</sub>SE model has been developed to estimate the risk of O<sub>3</sub> damage to the European vegetation and it is capable of providing flux-modelling estimates according to UN-ECE LRTAP methodologies for effects-based risk assessment (Pihl-Karlsson et al. 2004; Emberson et al. 2007; Karlsson et al. 2007; Tuovinen et al. 2007).

Meteorological data, O<sub>3</sub> concentration and plant-specific characteristics (e.g. physiological and phenological) are three basic groups of input data that enter into the model for the estimation of O<sub>3</sub> flux to the vegetated surfaces (Büker et al. 2012). The stomatal conductance ( $G_{sto}$ ) is one of the

most important and key parameters of the DO<sub>3</sub>SE model. The detailed description of the algorithm of  $G_{sto}$  calculation is given in the manual for modelling and mapping of the critical level exceedance (UN-ECE 2004).

The stomatal flux of O<sub>3</sub> ( $Fst$ ) is modeled using an algorithm incorporating the effects of meteorological conditions (air temperature, vapour pressure deficit, light); soil and plant water (soil water potential, available water content); plant phenology and O<sub>3</sub> concentration on the maximum stomatal conductance measured under the optimal conditions.  $Fst$  is the instantaneous flux of O<sub>3</sub> through the stomata pores per unit projected leaf area (PLA) and refers specifically to the sunlight leaves at the top of the canopy. As there is strong biological support for the use of a threshold to represent the detoxification capacity of the trees (Karlsson et al. 2007), the expert judgement was used to set  $Y$  to 1 nmol m<sup>-2</sup> PLA s<sup>-1</sup> for the forest trees (Mills et al. 2011). The model calculation of the stomatal flux is based on the assumption that the concentration of O<sub>3</sub> (nmol m<sup>-3</sup>) at the top of the canopy  $c(z1)$  measured in the tree height ( $z1$ ) represents a reasonable estimate of O<sub>3</sub> concentration at upper surface of the laminar layer. Stomatal O<sub>3</sub> flux  $Fst$  (nmol m<sup>-2</sup> PLA s<sup>-1</sup>) is given by (UN-ECE 2004):

$$Fst = c(z1) * Gsto * (rc / (rb + rc)) \quad [1]$$

where  $Gsto$  is the stomatal conductance for O<sub>3</sub> (m s<sup>-1</sup>),  $rb$  and  $rc$  are the quasi-laminar resistance and the leaf surface resistance (s m<sup>-1</sup>), respectively.  $PLA$  is the abbreviation of Projected Leaf Area.

The stomatal conductance can be calculated as:

$$G_{sto} = g_{max} * f_{phen} * f_{light} * \max\{f_{min}, (f_{temp} * f_{VPD} * f_{SWP})\} \quad [2]$$

where  $g_{max}$  is the species-specific maximum stomatal conductance (mmol O<sub>3</sub> m<sup>-2</sup> PLA s<sup>-1</sup>),  $f(phen, light, min, temp, VPD, SWP)$  are the parameters determining the effect of the environment and phenophase on the stomatal conductance. The detailed description of the algorithm and derivation of the physical relationships for the final calculation is given in the manual for modelling and mapping of  $CLef$  level exceedance (Mills et al. 2011).

The phytotoxic ozone doses ( $POD_Y$ ) is the accumulated value of the stomatal fluxes that exceed the threshold  $Y$  nmol m<sup>-2</sup> s<sup>-1</sup> during the vegetation season. It is calculated according to the formula:

$$POD_Y = \Sigma(1; n) [Fst - Y] \quad [3]$$

for  $Fst \geq Y$  with the accumulation of the hourly stomatal O<sub>3</sub> flux during the whole vegetation season (defined for the tree species and year of the assessment).  $Fst$  is the hourly mean stomatal O<sub>3</sub> flux (nmol m<sup>-2</sup> s<sup>-1</sup>) and  $n$  is the number of hours within the accumulation period. The threshold  $Y$  is defined as species-specific, the actual value for forest trees is proposed to 1 nmol m<sup>-2</sup> PLA s<sup>-1</sup>, the  $CLef$  of  $POD_Y$  is proposed to be 8 mmol m<sup>-2</sup> PLA for spruce (evergreen coniferous) with expected biomass increment reduction of 4 and 2% respectively (Mills et al. 2011).

Besides  $POD_Y$ , the exceedance of  $CLec$  of exposition index AOT40 was calculated for all experimental sites. The AOT40 for forests is the accumulated excess of the hourly ozone concentrations above 80 µg m<sup>-3</sup> between 8:00 and

20:00 CET over the period April–September (Directive 2008/50/EC). This indicator quantifies only the ozone exposure, i.e. not the effective ozone uptake by (and therefore the damage caused to) vegetation. In this study, AOT is the sum of the concentrations over the threshold value  $X$  calculated for the daily hours during the vegetation season according to the equation:

$$AOTX = \Sigma(1; n) [C - X] \quad [4]$$

for  $C \geq X$ , where  $C$  is the hourly mean O<sub>3</sub> concentration (ppb),  $n$  is the number of daily hours in the accumulation period, and  $X$  is the threshold value for forest ecosystems being 40 ppb.  $CLec$  of AOT40 was set to 5,000 ppb h (Directive 2008/50/EC). In the past, the value 10,000 ppb h was used. The exceedances of  $CLef$  for  $POD_1$  and  $CLec$  for AOT40 are calculated for the main tree species Norway spruce (*Picea abies* L. Karst.).

The parameterisation of DO<sub>3</sub>SE model reflects the recommendations in different scientific papers, the generic values are also given in manual ICP Modelling and Mapping (UN-ECE 2010), for some of them it is possible to assess by field measurement to be species specific and also site specific. More specific and detail information about model parameterisation is included in the Appendix.

## 3. Results

### 3.1. Meteorological data and weather conditions

Information on the development of meteorological parameters is important not only for the interpretation of the measured ozone data but also as key input into the model of stomatal ozone fluxes. In the High Tatra Mts., growing season 2014 (GS 2014) started after the snowmelt (March/April) and depending on the altitude continued until the late autumn (October/November). The statistical characteristics of the hourly weather data measured at the selected field sites in the High Tatra Mts. from April to October 2014 are included in the Table 2. The mean air temperature varied in interval from 7.5 to 12.0 °C and reached maxima up to 30 °C. Values were in line with the normal course of climate data (Fig. 2). The calculated values of the vapour pressure deficit (VPD) were under the limit level (VPD\_min, 3.00 kPa) for the minimal stomatal conductance (Fig. 2) that illustrates the favourable air humid conditions for the stomatal flux. The precipitation sums varied between 918 and 1,370 mm depending on the altitude of the site (Table 2). During the given GS period, the extraordinary weather events occurred. In May there was intensive heavy rain for two days and there fell about 100–200 mm. The windstorm at high altitudes (the maximum observed gust has achieved value of 42 m s<sup>-1</sup>) resulted in flooding and forest windfall, especially in the NW area above the Podmuráň experimental site (PDM). On the other hand, the SE foothill area was affected by an exceptional long dry event in June. A rainless or light rain period lasted 38 days from 22<sup>th</sup> May to 28<sup>th</sup> June with a very low precipitation sum of 19 mm at the Stará Lesná experimental site. The next wet event started on 29<sup>th</sup> June and continued for the next 34 days. During this period, the total

amount of precipitation reached a high value of 295 mm. July was a very wet month with a mean monthly temperature slightly above normal in the High Tatra Mts. as well as in whole territory of Slovakia. The weather at the end of summer and during autumn was relatively normal without unusual events. Frequently, the mean hourly wind speed values were up to a level of  $5 \text{ m s}^{-1}$  (Fig. 2), median ranged from  $0.7$  to  $1.9 \text{ m s}^{-1}$  (Table 2). For GS period, the sums of global radiation varied between the values from  $542 \text{ kWh m}^{-2}$  measured in the NW area (Kolové pleso) to  $848 \text{ kWh m}^{-2}$  observed in the SE area (Stará Lesná). The mean air pressure varied from  $82.3$  to  $92.4 \text{ kPa}$  and corresponded to the altitudinal position of the experimental sites.

### 3.2. Ozone data

The mean  $\text{O}_3$  values at the study sites aggregated over GS 2014 fluctuated from  $30.9$  to  $44.1 \text{ ppb}$  (Table 3). Prevailing humid weather in the summer of 2014 influenced the  $\text{O}_3$  formations in the atmospheric boundary layer, therefore the  $\text{O}_3$  concentrations for GS 2014 was relatively low. According to data from the Slovak air quality monitoring network (SHMI and ME SR 2015), the mean  $\text{O}_3$  concentrations for GS 2014 were lower than those in GS 2003 when the summer  $\text{O}_3$  event occurred (Bičárová et al. 2005) likely due to the heatwave and extraordinary drought in Europe (Fiala et al. 2003). Generally, by many physiological studies it was approved that the light causes plant stomata to open and darkness to close. At the sites under the altitude of  $1,600 \text{ m a.s.l.}$ , the mean  $\text{O}_3$  concentrations during the hours of sunlight (i.e. between  $07$ – $17 \text{ h}$ , when global radiation  $>50 \text{ W m}^{-2}$ ) were higher about  $30$ – $90\%$  than  $\text{O}_3$  mean concentrations during the night and weak sunlight hours ( $18$ – $06 \text{ h}$ ). These results suggest relevant stomatal  $\text{O}_3$  uptake into forest vegetation during daylight hours. On the contrary, at the high altitude site of Skalnaté Pleso ( $1,778 \text{ m a.s.l.}$ ) the values of ozone concentrations were higher by approximately  $1.7 \text{ ppb}$  during the nights in comparison to the sunlight part of day. Nevertheless, the mean  $\text{O}_3$  values for both sunlight and night part of day at this site exceeded a level of  $40 \text{ ppb}$ . Maximal hourly  $\text{O}_3$  concentrations occurred at sites on the northern slope ( $75.7$ – $88.0 \text{ ppb}$ ) were higher in comparison with sites on the southern slope ( $70.5$ – $78.1 \text{ ppb}$ ). Lower  $\text{O}_3$  maxima on south-facing slope may be associated with large deforestation and reduction of biogenic  $\text{O}_3$  precursors after wind disaster (Bičárová et al. 2015).

### 3.3. Plant-specific parameters and $\text{POD}_1$

The descriptive statistics of  $Gsto$  data estimated by  $\text{DO}_3\text{SE}$  model for all 5 experimental sites in the High Tatra Mts. during GS 2014 are included in Table 4. The modeled  $Gsto$  values reached maxima up to  $115 \text{ mmol m}^{-2} \text{ s}^{-1}$ . Over the GS 2014,  $Gsto$  mean ranged between  $21$  and  $28 \text{ mmol m}^{-2} \text{ s}^{-1}$ , during the sunlight hours ( $07$ – $17 \text{ h}$ ) mean values were nearly twice higher. Night-time mean  $Gsto$  did not exceed level of  $10 \text{ mmol m}^{-2} \text{ s}^{-1}$ . As the growing season of 2014 was mostly humid the impact of water stress on plant

stomatal conductance was minimal with the exception of June at the foothills represented by the Stará Lesná site. Generally, the stomatal conductance gradually increases as the temperature increases reaching a peak and then gradually declines as the temperature increases beyond the optimum, whilst the stomatal conductance increases rapidly as light levels increase, reaching a maximum at relatively low light levels and maintaining that maximum as light level increase further (UN-ECE 2004).

$\text{DO}_3\text{SE}$  model estimation of  $Fst$  for the experimental sites in the High Tatra Mts. (Table 5) showed that the mean  $Fst$  values for GS 2014 were over the threshold value  $Y$  of  $1 \text{ nmol m}^{-2} \text{ PLA s}^{-1}$ . Nearly twice higher mean  $Fst$  calculated for the sunlight part of a day ( $07$ – $17 \text{ h}$ ) suggests intensive stomatal  $\text{O}_3$  uptake to the forest vegetation during the photosynthetic process. The elevation profile of mean values of  $\text{O}_3$ ,  $Gsto$  and  $Fst$  (Fig. 3) illustrates great increase of  $\text{O}_3$  concentration with altitude that is in contrast to slightly decrease of  $Gsto$  and nearly unchanged  $Fst$ .

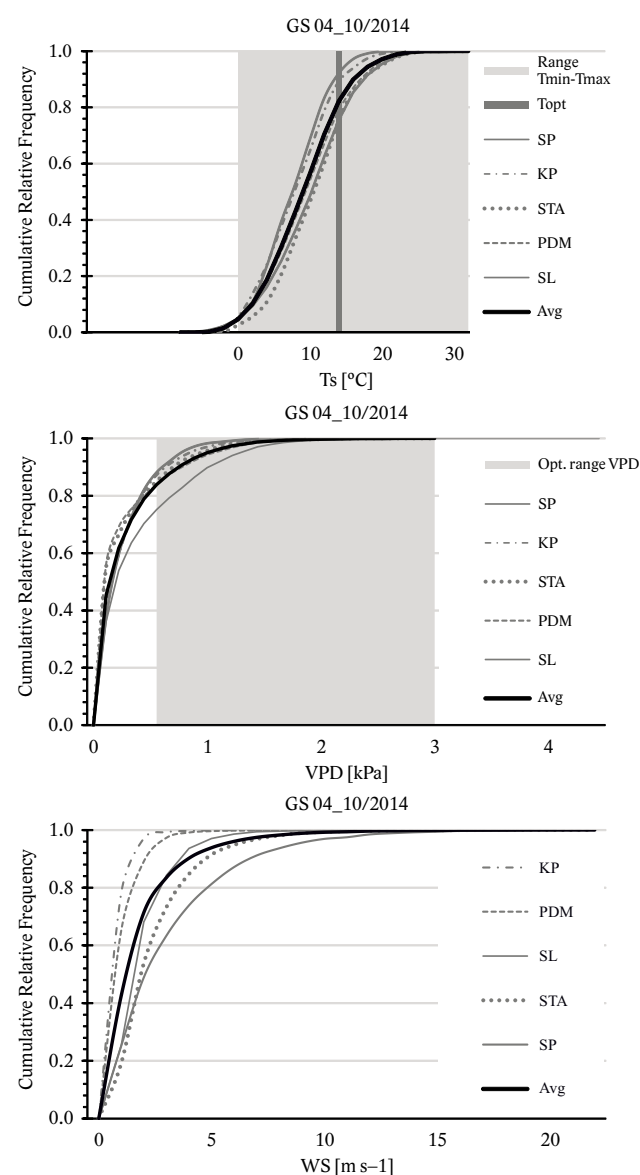

Fig. 2. Cumulative frequency distribution of hourly mean air temperature ( $T_s$ ), vapour pressure deficit (VPD) and wind speed (WS).

**Fig. 3.** Altitudinal relation of O<sub>3</sub> concentration (ppb), stomatal conductance ( $G_{sto}$  mmol m<sup>-2</sup> s<sup>-1</sup>) and stomatal flux ( $Fst$  nmol m<sup>-2</sup> PLA s<sup>-1</sup>) in the High Tatra Mts. averaged for GS 2014 (0–23 hours).

The model estimates for both AOT<sub>40</sub> (Fig. 4) and POD<sub>1</sub> (Fig. 5) for Norway spruce (*Picea abies* L. Karst) indicate the exceedance of  $CLec$  as well as  $CLef$  at all experimental sites in the High Tatra Mts. during GS 2014. Index AOT<sub>40</sub> was increasing with the altitude and reached the values from 6.2 ppm h in Stará Lesná (810 m a.s.l.) to 10.7 ppm h at Skalnáté Pleso near the timber line (1,778 m a.s.l.). The critical threshold ( $CLec$  of 5,000 ppb h) was exceeded at each considered sites in different date. First it was at the Skalnáté Pleso site in the first half of June due to a generally higher O<sub>3</sub> concentration for the higher altitude position. At the beginning of August, index AOT<sub>40</sub> was above  $CLec$  at all sites. POD<sub>1</sub> reached values from 13.6 mmol m<sup>-2</sup> PLA at site Kolové pleso (1,570 m a.s.l.) to 16.2 mmol m<sup>-2</sup> PLA at Skalnáté Pleso (1,778 m a.s.l.). The critical level  $CLef$  of 8 mmol m<sup>-2</sup> PLA recommended for the spruce protection was exceeded at all experimental plots during July, in around half of the growing season 2014.

**Fig. 4.** Accumulated ozone exposure index AOT40 [ppm h] and the concentration-based critical level (*CLec*) for effects of ozone on forests at experimental sites in the High Tatra Mts. during GS 2014.

**Fig. 5.** Cumulative stomatal flux of ozone  $POD_1$  [mmol m<sup>-2</sup> PLA] and stomatal flux-based critical level (*CLef*) for effects of ozone on forests at experimental sites in the High Tatra Mts. during GS 2014.

#### 4. Discussion

Phytotoxic effects of  $O_3$  on forest vegetation are hardly distinguishable by direct methods. Based on recent epidemiological studies, Norway spruce is not clearly affected by visible  $O_3$  injury (chlorotic mottling on the needles) and may be classified as an  $O_3$ -tolerant species (Nunn et al. 2002; Sicard et al. 2016). Critical levels of ozone concentrations could be described in different ways including concentration-based *CLec* for AOT40 and stomatal flux-based *CLef* for  $POD_Y$  that considers the stomatal conductance as the main control driver of  $O_3$  uptake by plants. Stomatal flux-based approach has not been applied yet in assessment of  $O_3$  impact on forest vegetation in Slovakia, mainly due to the extensive requirement of direct measurements and model input data. The presented results of pilot  $O_3$  measurements and model outputs of  $POD_1$  and AOT40 in the High Tatra Mts. achieved for the growing season of 2014 indicate vulnerability of forest vegetation to chronic and long-term exposure of  $O_3$  pollution in the Western Carpathian Mts. Our results are consistent with the findings of many previous research studies conducted in surrounding countries. For example, in the medium altitudes of forested mountains in Central Europe (in the Jizerské hory Mts.), the  $O_3$  exposure is also relatively high and comparable with the polluted sites in Southern Europe and in the higher altitudes (Hůnová et al. 2016). On the contrary, some areas of the Carpathian Mountains, in Romania and parts of Poland, as well as the Šumava and Brdy Mountains in the Czech Republic are characterized by low European background  $O_3$  concentrations (summer season means of 30 ppb). Other parts of the Carpathians, particularly the western part of the range (Slovakia, the Czech Republic and Poland), some of the Eastern (Ukraine) and Southern (Romania) Carpathians and the Jizerske Mountains have high  $O_3$  levels with the peak values >100 ppb and seasonal means of 50 ppb (Bytnerowicz et al. 2004). In the Czech Republic, the  $O_3$  flux over a Norway spruce forest was measured by the gradient method and the results showed that the total deposition and stomatal uptake of  $O_3$  significantly decreased the net ecosystem production (Zapletal et al. 2011).

As shown in our results, mean  $O_3$  concentrations are high enough to effective  $O_3$  uptake through stomata of coniferous trees supported by colder and wetter mountain climate favourable for open stomata processes. Both, simple concentration-based AOT40 and complex stomatal flux-based  $POD_1$  values exceeded critical levels during growing season. AOT40 more reflects increase of  $O_3$  concentration with altitude while  $POD_1$  in relation to *Gsto* and *Fst* takes into account meteorological conditions. The main difference between AOT40 and  $POD_1$  was found in the date (month) of exceedance of critical levels, particularly at site Skalnaté Pleso where the *CLec* value was exceeded in June (at the earliest date) and the *CLef* value was exceeded later in July 2014.

As confirmed by many researches, the high mountain regions are especially susceptible to the deposition of many industrial and agricultural pollutants undergoing atmospheric transport, through a process called orographic cold trapping (Hageman et al. 2015; Arellano et al. 2015). The influence of long-range transport of air pollutants on  $O_3$  concentration in the High Tatra Mts. was noticed e.g. during unusual drought and heatwave event in summer 2003 (Bičárová et al. 2005), when the values of  $O_3$  were significant higher than those observed within this study in wet GS 2014. The accumulated stomatal  $O_3$  uptakes calculated by model  $DO_3SE$  exceeded *CLef* during the growing season 2014 (April–October) and indicate the risk of  $O_3$  injury to spruce forest in the High Tatra Mts. Based on our results, the application of  $DO_3SE$  model in the High Tatra Mts. seems to be appropriate tool for monitoring of chronic  $O_3$  exposure,  $O_3$  deposition and stomatal  $O_3$  uptake to forest vegetation.

Innovative epidemiological assessment of forest responses to  $O_3$  reflecting flux-effect relationships includes species-specific *CLef* for forest protection against visible  $O_3$  injury (Sicard et al. 2016). New *CLef* for the forest protection against the visible  $O_3$  injury was calculated for  $O_3$  highly sensitive conifer *Pinus cembra*. In this case, the proposed value of *CLef* 19 mmol m<sup>-2</sup> represents the value  $POD_0$  accumulated for hours with a non-null global radiation (Sicard et al. 2016). However, visible injuries on the needles of many conifer spe-

cies, like Norway spruce (*Picea abies*) and Scots pine (*Pinus sylvestris*), are rare and cannot yet be reliably associated with O<sub>3</sub> in the field (Günthardt-Goerg 2001).

Currently the main tree species of interest in our research are Norway spruce (*Picea abies* L. Karst.), mainly for its economic relevance in the model area as well as the Mountain pine (*Pinus mugo* Turra), creating a timberline in the High Tatra Mts. Another ecologically valuable and endemic tree in the Tatra Mountains is Swiss stone pine (*Pinus cembra* L.) that occupies specific, relatively small areas close to the alpine tree line and is highly protected in the whole Tatra National Park. Therefore, in the next years the research priorities linking to study of O<sub>3</sub> effect on forest vegetation in the High Tatra Mts. will be focused on biomonitoring of conifer pine species, particularly *Pinus cembra* and *Pinus mugo*.

## 5. Conclusions

In recent decades, the considerably and progressive deterioration of forest health status in the Tatra National Park in Slovakia was observed. Synergy of biotic and abiotic disturbances has caused the degradation of the living forest, disruption of ecological relations and other functions of the forest environment. This study presents the results of the phytotoxic ozone doses (POD<sub>1</sub>) modeling for Norway spruce forests in the High Tatra Mts. – the highest part of Western Carpathians. The DO<sub>3</sub>SE model outputs for the growing season 2014 indicate an excessive stomatal O<sub>3</sub> uptake by spruce forests at five experimental sites distributed in the altitudinal range from 810 to 1,778 m a.s.l. along the vertical and spatial profile in the High Tatra Mts. Accumulated stomatal O<sub>3</sub> flux i. e. POD<sub>1</sub> exceeded *CLef* at all considered sites during July 2014, approximately in the middle of considering growing season. Potential detrimental effect of O<sub>3</sub> is shown also by AOT40 index that exceeded *CLec* differently for each experimental site from the half of June to the end of August 2014. Both POD<sub>1</sub> and AOT40 show a high phytotoxic potential of O<sub>3</sub> pollution in the forest environment of the highest part of Carpathian Mountains. The deposition models such as DO<sub>3</sub>SE that simulate the total and stomatal O<sub>3</sub> fluxes was in our study approved as an appropriate tool for the assessment of critical O<sub>3</sub> level exceedance and risk of secondary air pollution for the mountain forest ecosystems.

## Acknowledgements

This work was supported by the Slovak Research and Development Agency under the contracts No. APVV-0429-12 and APVV-0111-10, and by the Grant Agency of the Slovak Republic (VEGA, No. 2/0053/14). The authors are grateful to the Slovak Hydrometeorological Institute for providing of meteorological and EMEP data. The development of DO<sub>3</sub>SE model interface has been made possible through funding provided by the UK Department of Environment, Food and Rural Affairs (Defra) and through institutional support provided to the Stockholm Environment Institute from the Swedish International Development Agency (Sida).

## Appendix – Supplementary Information to paper

### Details to section: Material and methods

Model parametrisation of input variables is performed by creation of DO<sub>3</sub>SE model project. For each experimental site, creation of new project is needed e.g. Appendix 1 includes input parameters for Norway spruce forest in Stará Lesná. The structure of model project consists of ten items explained in next paragraphs.

[1] **The model introduction** is related to the opening of a new or selected project that could be modified according to the location properties, vegetation type, environmental interactions, growing season, and phenology.

[2] The input dataset format processed the CSV data file, including the hourly values of **O<sub>3</sub> concentration and meteorological variables** as specified in the Table 1 and with respect to the required units. The Vapour Pressure Deficit (VPD, kPa) was calculated from the air temperature and relative humidity measurements. Where O<sub>3</sub> and meteorological data were missing for periods of several hours, data gaps were filled using a linear interpolation between adjacent data points.

[3] **The location properties** cover the geographical coordinates and typical soil texture (Appendix 1): silt loam (medium coarse), sandy loam (coarse) and loam (medium) where the soil resistance term to water vapour flow (*R<sub>soil</sub>*) is 200 s m<sup>-1</sup>. *R<sub>soil</sub>* is a complex function of the vertical soil water distribution. An important feature of evaporation from soil is a fast reduction due to the drying of the uppermost soil layer after rainfall. For a fully wet soil *R<sub>soil</sub>* value is equal to 100 s m<sup>-1</sup> (Grünhage & Haenel 2008).

[4] **Measured data** were optimised and recalculated for individual heights of O<sub>3</sub> and wind speed measurements. For forests, O<sub>3</sub> concentrations must often be derived from measurements made over grassy areas or other land-cover types. O<sub>3</sub> measured at variable heights over land-use were used to estimate the O<sub>3</sub> concentration at a referenced height by application of the gradient profile appropriate for the desired land use (UN-ECE 2004). Soil water measurement depth (d, 0.5 m) allows the model to calculate soil water data for a particular depth which can then be compared to the real-world data.

[5] **Vegetation characteristics** were linked to the following parameters: Canopy height (h, 20 m); Root depth (dr, 1 m); Leaf dimension (Lm, 0.05m); Albedo (0.12); Species specific maximum stomatal conductance (g<sub>max</sub>, 125 mmol O<sub>3</sub> m<sup>-2</sup> PLA s<sup>-1</sup>); Sun/shade factor (1); Receptor specific value (f<sub>min</sub>, 0.16); External plant cuticle resistance (R<sub>ext</sub>, 2,500 s m<sup>-1</sup>); Threshold Y for POD<sub>Y</sub> (1.0 nmol m<sup>-2</sup> s<sup>-1</sup>); Closed stomata conductance (G<sub>sto0</sub>, 30,000 μmol m<sup>-2</sup> s<sup>-1</sup>); Species-specific sensitivity to An (m, 16.83); Maximum catalytic rate at 25 °C (V<sub>cmax</sub>, 30 μmol m<sup>-2</sup> s<sup>-1</sup>); Maximum rate of electron transport at 25 °C (J<sub>max</sub> 60, μmol m<sup>-2</sup> s<sup>-1</sup>).

[6] **The environmental response** includes: A parameter related to the function  $f_{light}$  and the photosynthetic photon density (ligh\_a, 0.010); Minimum temperature (T<sub>min</sub>, 0 °C); Optimum temperature (T<sub>opt</sub>, 14 °C); Maximum temperature (T<sub>max</sub>, 35 °C); Vapour Pressure Deficit for maximal stomatal conductance (VPD<sub>max</sub>, 0.50 kPa); Vapour Pressure Deficit for minimal stomatal conductance (VPD<sub>min</sub>, 3.00 kPa); Critical daily VPD sum (VPD<sub>crit</sub>, 1,000 kPa); Soil water potential for minimal stomatal conductance (SWP<sub>min</sub>, -0.50 MPa); Soil water potential for maximal stomatal conductance (SWP<sub>max</sub>, -0.05 MPa).

[7] **The model option** allows an alternate choice of different methods for calculating the same factors. For the simulation in this work, the following ones were selected: Multiplicative stomatal conductance model; Estimated leaf temperature; Not used the fO<sub>3</sub> method in the calculation of leaf G<sub>sto</sub>; Linear (SWP<sub>min</sub>, SWP<sub>max</sub>) fSWP calculation; Use of supporting interface fSWP for calculating the effect of soil water availability on stomatal conductance; Steady-state method of Leaf Water Potential calculation – the steady state model controls water flux on an hourly time-step using an estimation of LWP based on the daily SWP and plant transpiration of the previous hours (Büker et al. 2012).

[8] **The season** was set on the duration of Growing Season (GS). Duration of GS from the start (SGS) to the end (EGS) estimated according to the latitude function with respect to the forest vegetation. Leaf Area Index at SGS (LAI<sub>a</sub>, 3.5 m<sup>2</sup> m<sup>-2</sup>); First mid-season LAI (LAI<sub>b</sub>, 4.0 m<sup>2</sup> m<sup>-2</sup>); Second mid-season LAI (LAI<sub>c</sub>, 3.8 m<sup>2</sup> m<sup>-2</sup>); Leaf Area Index at EGS (LAI<sub>d</sub>, 3.5 m<sup>2</sup> m<sup>-2</sup>); Period from LAI<sub>a</sub> to LAI<sub>b</sub> (LAI<sub>1</sub>, 25 days); Period from LAI<sub>c</sub> to LAI<sub>d</sub> (LAI<sub>2</sub>, 30 days); Stem Area Index calculation for forest.

[9] **Phenology** is focused on the configuration of the *Fphen* function. For the forests species, the *fphen* parameterisation is based on data describing the increase and reduction in *G<sub>sto</sub>* with the onset and end of the physiological activity (CLR-TAP 2004). We assumed that *fphen* was 1 throughout the growing season, i.e. the POD<sub>Y</sub> accumulation period. *Fphen* at SGS (fphen<sub>a</sub>, 0.0); First mid-season *Fphen* (fphen<sub>b</sub>, 1.0); Second mid-season *Fphen* (fphen<sub>c</sub>, 1.0); Third mid-season *Fphen* (fphen<sub>d</sub>, 1.0); *Fphen* at EGS (fphen<sub>e</sub>, 0.0); Period from fphen<sub>a</sub> to fphen<sub>b</sub> (fphen1, 0 days); Parameters of SWP limitation are set to 0, the model reverts to a simpler version.

[10] **Leaf phenology (Leaf<sub>fphen</sub>)**: the calculation is the same as of *Fphen*.

**Appendix 1.** Input parameters using for model calculation of  $POD_1$  for Norway spruce forest at Stará Lesná experimental site during growing season 2014.

DO <sub>3</sub> SE model: INPUT parameters			
Location properties		Measurement data	
Latitude	49.15	O <sub>3</sub> measurement height-recalculated [m]	20
Longitude	20.28	O <sub>3</sub> measurement canopy height [m]	20
Elevation [m a.s.l.]	810	Wind speed measurement height- recalcul. [m]	20
Soil texture	Silt loam (medium coarse)	Wind speed measurement canopy height [m]	20
Rsoil [s/m]	200	Soil water measurement depth [m]	0.5
Environmental response		Vegetation characteristics	
light_a	0.01	Canopy height [h, m]	20.00
T_min °C	0.00	Root depth (root, m)	1.00
T_opt °C	14.00	Leaf dimension [Lm, m]	0.08
T_max °C	35.00	Albedo (fraction)	0.12
VPD for max.g [VPD_max, kPA]	0.50	gmax [mmol O <sub>3</sub> /m <sup>2</sup> PLA/s]	125.00
VPD for min.g [VPD_min, kPA]	3.00	Sun/shade factor (fraction)	1.00
SWP for min.g [SWP_min, Mpa]	-0.50	fmin (fraction)	0.16
SWP for max.g [SWP_max, Mpa]	-0.05	External plant cuticule resistance [Rext, s/m]	2500.00
Model options		Threshold Y for PODy [nmol/m <sup>2</sup> /s]	1.00
Stomatal conductance model	Multiplicative	Closed stomata conductance [Gsto0, umol/m <sup>2</sup> /s]	30000.00
Leaf temperature calculation	Estimate	Species-specific sensitivity to An [m, dimensionless]	16.83
fO <sub>3</sub> calculation	Not used (f3=1)	Maximum catalytic rate at 25 °C [Vcmax, umol/m <sup>2</sup> /s]	30.00
Soil water influence on Gsto	Use fSWP	Maximum rate of electron transport at 25°C [Jmax, umol/m <sup>2</sup> /s]	60.00
LWP calculation	steady-state	fphen	
fSWP calculation	Linear	fphen_a	0.0
Season		fphen_b	1.0
SGS/EGS method	Latitude function	fphen_c	1.0
Star of growing season SGS	112	fphen_d	1.0
End of growing season EGS	291	fphen_e	0.0
LAI at SGS [LAI_a, m <sup>2</sup> /m <sup>2</sup> ]	3.5	fphen_1	0
First mid-season [LAI_b, m <sup>2</sup> /m <sup>2</sup> ]	4.0	fphen_limA	0
Second mid-season LAI [LAI_c, m <sup>2</sup> /m <sup>2</sup> ]	3.8	fphen_2	200
LAI at EGS [LAI_d, m <sup>2</sup> /m <sup>2</sup> ]	3.5	Fphen 3	200
Period from LAI_a to LAI_b [LAI_1, days]	25	fphen_limB	0
Period from LAI_c to LAI_d [LAI_1, days]	30	fphen_4	0
SAI calculation	Forest	Leaf fphen calculation	Same as Fphen
